Red blood cells in humans-and most other mammals-have a tendency to form aggregates with a characteristic face-to-face morphology, similar to a stack of coins. Known as rouleaux, these aggregates are a normally occurring phenomenon and have a major impact on blood rheology. What is the underlying mechanism that produces this pattern? Does this real

Abstract. Human red blood cells (RBCs) aggregate under low shear conditions, which significantly modulates flow resistance and tissue perfusion. A higher aggregation tendency in blood thus serves as an important clinical indicator for the screening of cardiovascular disorders. Conventional ways of measuring RBC aggregation still require large sample volumes, cumbersome manual procedures, and expensive benchtop systems.

With these properties, RBC aggregation would also be identifiable with poor circulation in the small capillaries.

Addition of D9.6 to MM blood reverts the enhanced aggregation toward normal. Discussion: The findings that RBC aggregation changes in the following order: MM blood > normal RBCs in MM plasma > control blood sample, suggest that surface-active plasma molecules play a role in enhanced aggregation in MM. The surface concentration of these molecules and hence RBC aggregability is reduced in the presence of dextrans due to their competitive adsorption onto RBC membrane.

Erythrocytes aggregate in a special way, forming rouleaux. Rouleaux are stacks of erythrocytes which form because of the unique discoid shape of the cells in vertebrate body. The flat surface of the discoid RBCs give them a large surface area to make contact and stick to each other; thus, forming a rouleau. Rouleaux formation takes place only in suspensions of RBC containing high-molecular, fibrillar proteins or polymers in the suspending medium. The most important protein causing rouleaux format

Red blood cells (RBCs) participate in acute coronary occlusion, mainly under conditions of lower shear rate, for example, within the microcirculation in the peri-infarct domain of myocardium. Under in vitrostatic conditions, RBCs in normal human blood form loose aggregates with a characteristic morphology, similar to a stack of coins.

Red blood cells (RBCs) in physiological conditions are capable of deforming and aggregating. However, both deformation and aggregation are seldom considered together when modeling the rheological behavior of blood. This is particularly important since each mechanism is dominant under specific conditions. To address this void, we herein propose a new model that accounts for the

Methods: In the present study, we evaluated the degree of red blood cell (RBC) aggregation at a low

shear rate robustly by introducing two new parameters determined from changes in the scattering power spectrum of the echoes from the intravascular lumen before and after cessation of blood flow. We also considered the clinical significance of these parameters and the change in sizes estimated by the conventional method by comparing them with the blood glucose level obtained just before the ...

Erythrocyte aggregation is one of the major determinants of in vivo blood flow and blood viscosity at low shear rates. During the aggregation process, erythrocytes reversibly form rouleaux or network of aggregates (1). Two mechanisms were suggested to explain the erythrocytes aggregation, protein bridging or by protein depletion mechanisms (2-4).
