Using Checksums To Detect Data Corruption

Checksum serves as a unique identifier for the data (a file, a text string, or a hexadecimal string). If the data changes then so does the checksum value. This makes it easy to verify the integrity of the data. To test data integrity, the sender of the data calculates checksum value by taking the sum of the binary data transmitted.

When the receiver gets this data, a new checksum is calculated and compared with the existing checksum. A non-match indicates an error. Error Detection by Checksums. For error detection by checksums, data is divided into fixed sized frames or segments. Sender's End – The sender adds the segments using 1's complement arithmetic to get the sum. It then complements the sum to get the checksum and sends it along with the data frames.

Error-Detecting Codes - Checksums

A checksum algorithm is used to check for errors in data transmission. It works by calculating a numerical value based on the number of bits in a packet of data. This numerical value is attached to the packet. When the packet reaches its

destination, the same checksum algorithm is applied to the data it contains.

Error Detection using Checksums - Belper Computing

Error detection using checksum method involves the following steps- Step-01: At sender side, If m bit checksum is used, the data unit to be transmitted is divided into segments of m bits. All the m bit segments are added. The result of the sum is then complemented using 1's complement arithmetic. The value so obtained is called as checksum. Step-02:

One important aspect in using checksums to detect corrupted data is

that the checksums should be as unique as possible to avoid the case where the data can change without the checksum changing. There are many ways to compute a checksum such as md5sum, sha1sum, sha2 algorithms (sha256, sha384, sha512) as well as others. These checksums algorithms produce a different length checksum with longer checksums requiring more computational work.
